Received May 7, 2001

Abstract: Synchrotron-based high-resolution photoemission, X-ray absorption near-edge spectroscopy, and first-principles density functional (DF) slab calculations were used to study the interaction of NO₂ with a TiO₂(110) single crystal and powders of titania. The main product of the adsorption of NO₂ on TiO₂(110) is surface nitrate with a small amount of chemisorbed NO₂. A similar result is obtained after the reaction of NO₂ with polycrystalline powders of TiO₂ or other oxide powders. This trend, however, does not imply that the metal centers of the oxides are unreactive toward NO₂. An unexpected mechanism is seen for the formation of NO₃. Photoemission data and DF calculations indicate that the surface nitrate forms through the disproportionation of NO₂ on Ti sites ($2\text{NO}_{2,\text{ads}} \rightarrow \text{NO}_{3,\text{ads}} + \text{NO}_{\text{gas}}$) rather than direct adsorption of NO₂ on O centers of titania. Complex interactions take place between NO₂ and O vacancies of TiO₂(110). Electronic states associated with O vacancies play a predominant role in the bonding and surface chemistry of NO₂. The adsorbed NO₂, on its part, affects the thermochemical stability of O vacancies, facilitating their migration from the bulk to the surface of titania. The behavior of the NO₂/titania system illustrates the importance of surface and subsurface defects when using an oxide for trapping or destroying NO_x species in the prevention of environmental pollution (DeNO_x operations).

I. Introduction

Nitrogen oxides (NO_x), one of the most harmful environmental pollutants,¹ are formed in automotive engines and industrial combustion systems when air is used as an oxidant agent.² In the atmosphere, nitrogen oxides are a serious health hazard for the human respiratory system and contribute to the generation of smog and acid rain.¹ Although the elimination of nitrogen oxides from gas streams (DeNO_x operations) has been a major concern for the past three decades, recently research in this area has intensified.^{2–4} In part, this is motivated by the fact that there is evidence that emission of these noxious vapors into the atmosphere has increased.^{4a,5} New and more stringent

regulations on NO_x emissions emphasize the need for more efficient catalysts or sorbents for pollution control.²

NO₂ is produced in combustion processes under oxygen-rich conditions. Emerging technologies favor the formation of NO₂ instead of NO during the combustion of fuels because the higher reactivity of NO₂ makes easier subsequent DeNO_x operations.^{4b,6} NO₂ is a radical molecule,⁷ with a large electron affinity (~2.3 eV⁸), that can bond to metal centers via O, N, or a combination of both.⁹ It is known that the chemistry of NO₂ on metal surfaces is rich.^{10,11} The adsorbed molecule can undergo partial ($\text{NO}_2 \rightarrow \text{NO} + \text{O}$) or complete dissociation ($\text{NO}_2 \rightarrow \text{N} + 2\text{O}$), or disproportionate into NO₃ species ($2\text{NO}_2 \rightarrow \text{NO}_3 + \text{NO}$). Oxides can be very useful as sorbents or catalysts for trapping or destroying NO₂ and other NO_x species.^{2–4} For example, oxides are used in NO_x storage technologies where the release of NO₂ at high temperatures is a key issue.^{4c,12} In addition, oxides are able to catalyze the reduction of NO₂ by alkanes.^{2,4b,6} However,

very little is known about the basic chemistry of NO₂ on oxide surfaces.¹³ A few surface science studies have been carried out on epitaxial oxide films (Cr₂O₃,^{14,15} MgO,¹⁶ CeO₂,^{16,17} Ce_{0.8}-Zr_{0.2}O₂)¹⁷ grown on metal or oxide supports, and on a ZnO-(0001)-Zn single crystal.¹⁸ There is a clear need to obtain a more complete understanding of the bonding and behavior of NO₂ on oxides.^{6,12,13}

Titania is an important component in NO_x storage–reduction catalysts.^{4c–h} In the present work, we use synchrotron-based high-resolution photoemission, X-ray absorption near-edge spectroscopy (XANES), and first-principles density-functional (DF) slab calculations to study the interaction of NO₂ with a TiO₂(110) single crystal and powders of titania. The (110) face of TiO₂ in the rutile crystal structure is interesting because it exposes metal and oxygen atoms, allowing a direct comparison of the reactivity of these adsorption sites. Our results show an unexpected mechanism for the formation of NO₃ on titania. A very important issue in oxide catalysis is the role of surface defects in determining the activity and selectivity of the catalyst.^{19,20} It is well known how to generate O vacancies in the TiO₂(110) substrate.^{13,21} Combining experiments and theoretical calculations, we examined in detail the bonding of NO₂ to vacancy structures on the oxide surface. The presence of O vacancies leads to complex interactions in the NO₂/TiO₂(110) system. On one hand, O vacancies induce new electronic states in the oxide that favor the adsorption of NO₂ and drastically alter the surface chemistry of this molecule. On the other hand, the adsorbed NO₂ substantially affects the thermochemical stability of the O vacancies in the surface. Our results clearly show that NO_x species induce the migration of O vacancies from the bulk toward the surface of an oxide. These phenomena can control the efficiency of an oxide as a sorbent or catalyst in DeNO_x operations.

II. Experimental and Theoretical Methods

II.1. Photoemission Experiments. The photoemission experiments for the adsorption of NO₂ on the (110) face of TiO₂ in the rutile crystal structure were performed in a standard ultra-high-vacuum (UHV) chamber (base pressure $\sim 6 \times 10^{-10}$ Torr) that is part of the U7A beamline of the National Synchrotron Light Source (NSLS) at Brookhaven National Laboratory.^{16,17,22} This UHV chamber contains a hemispherical electron energy analyzer with multichannel detection, instrumentation for low-energy electron diffraction (LEED), a quadrupole mass spectrometer, and a dual-anode Mg/Al K α source. The N 1s and valence spectra were taken using a photon energy of 500 eV, whereas a photon energy of 625 eV was used to collect the Ti 2p and O 1s data. The binding energy scale of the photoemission spectra was

calibrated by the position of the Fermi edge.²² The overall instrumental resolution in the photoemission experiments was ~ 0.35 eV.

Mounting of the TiO₂(110) sample in the UHV chamber was done according to the procedure described in ref 23. In short, the oxide sample was sandwiched between Ta plates that were spot-welded to two Ta heating legs of a manipulator capable of cooling to 80 K and heating to 1100 K. The TiO₂(110) crystal was cleaned by ion bombardment with 1 keV Ne⁺ ions at room temperature, followed by annealing in UHV for 10 min at 970 K.^{21,22} This sample treatment produced a (1 \times 1) LEED pattern, and previous studies using scanning tunneling microscopy²¹ and photoemission²³ have shown that the resulting surface has O vacancies with a density of $\sim 7\%$. NO₂ was dosed to the TiO₂(110) surface through a glass-capillary array doser^{16–18} positioned to face the sample at a distance of ~ 2 mm. The NO₂ exposures are based on the ion gauge reading and were not corrected for the capillary array enhancement.

II.2. XANES Experiments. Powders of the rutile and anatase phases of TiO₂ plus other oxides (MgO, CeO₂, Cr₂O₃, Fe₂O₃, CuO, ZnO) were exposed to NO₂ in an RXM-100 instrument from Advanced Scientific Designs. This was done in a reaction cell (batch-reactor mode) at 300 K for 15 min with constant gas pressures of 400–500 Torr. All the oxide powders were obtained from commercial sources and had a purity in excess of 99%. The oxides were cleaned before exposure to NO₂ by heating (400–700 K) in a vacuum or in the presence of O₂ until they displayed typical O K-edge XANES and core-level photoemission spectra.^{18,20c} Beamline U7A of the NSLS was used to collect the N and O K-edge XANES data. These spectra were taken in the electron-yield mode by using a channeltron multiplier located near the sample surface. The energy resolution was close to 0.3 eV.

II.3. Theoretical Methods and Models. The first-principles density functional (DF) calculations reported in section III were performed using the commercial version of the CASTEP code²⁴ available from Molecular Simulations Inc. CASTEP has an excellent track record in accurate prediction of geometry and energetics for oxide systems.^{15,16,22,24–28} In this code, the wave functions of valence electrons are expanded in a plane wave basis set with *k*-vectors within a specified energy cutoff *E*_{cut}. Tightly bound core electrons are represented by nonlocal ultrasoft pseudopotentials.²⁹ Brillouin zone integration is approximated by a sum over special *k*-points chosen using the Monkhorst–Pack scheme.³⁰ The exchange-correlation contribution to the total electronic energy is treated in a spin-polarized generalized-gradient corrected (GGA) form of the local density approximation (LDA).³¹ In all the calculations, the kinetic energy cutoff *E*_{cut} and the density of the Monkhorst–Pack *k*-point mesh were chosen high enough to ensure convergence of the computed structures and energetics. Since the DF calculations were performed at the GGA level, one can expect good predictions for the bonding energies of the NO₂ molecule on TiO₂.^{31,32} For the interaction of NO with oxides, DF-GGA calculations predict adsorption energies within an accuracy of 5 kcal/mol.^{25a,33} In any case, in this work our main interest is in qualitative trends in the energetics, and not in absolute values. For each

Figure 1. N 1s spectra acquired after depositing a multilayer of NO₂ on TiO₂(110) at 100 K, with subsequent heating to higher temperatures. The electrons were excited using a photon energy of 500 eV.

optimized structure, the partial charges on the atoms were estimated by projecting the occupied one-electron eigenstates onto a localized basis set with a subsequent Mulliken population analysis.^{34,35} Mulliken charges have well-known limitations³⁶ but are nevertheless useful as a qualitative tool.

III. Results

III.1. Reaction of NO₂ with TiO₂. Figure 1 shows N 1s photoemission spectra acquired after depositing a multilayer of NO₂ on a TiO₂(110) surface at 100 K with subsequent annealing to higher temperatures. Upon dosing of nitrogen dioxide at 100 K, two clear features are observed. The peak near 403.5 eV corresponds to chemisorbed NO₂,¹⁶ whereas the peak at ~406 eV can be assigned to physisorbed NO₂ (or N₂O₄ dimers^{11b}) since it disappeared after heating above 150 K.^{17,18} For small and medium exposures of NO₂ gas (not shown), only the N 1s signal of chemisorbed NO₂ was detected at 100 K. By 200 K, the intensity of the peak for chemisorbed NO₂ in Figure 1 has decreased, and a new strong peak is seen at ~407 eV that matches the binding energy position reported for chemisorbed NO₃.^{16,18} Following a common line of thought,³⁷ one could assume that the nitrate is formed by direct interaction of NO₂ with O atoms of the oxide surface:

But, if this is the case, it is difficult to understand why NO₂ is

Figure 2. O 1s spectra taken after adsorbing a multilayer of NO₂ on TiO₂(110) at 100 K, with subsequent heating to higher temperatures. A photon energy of 625 eV was used to take these spectra.

bonded to Ti sites at 100 K instead of reacting with O to form the more stable NO₃ species. The validity of this hypothesis will be tested by means of DF calculations in section III.2. In Figure 1, heating to 300 K removes the signal for NO₂, and features for atomic nitrogen begin to appear near 399 eV.^{16,18} From 300 to 400 K, there is a decrease in the signal for NO₃ and an increase in the signal for N. Around 500 K, only a small amount of NO₃ is seen on the surface, which completely disappears upon final heating to 600 K.

O 1s spectra for the adsorption of NO₂ on TiO₂(110) are shown in Figure 2. The clean oxide exhibits a peak near 529.2 eV. This peak is almost completely attenuated after deposition of a multilayer of NO₂ on the surface at 100 K. The physisorbed NO₂ desorbs upon heating to 200 K, leaving an O 1s spectrum with peaks for TiO₂ (~528.7 eV) and chemisorbed NO_x species (~531.3 eV). The binding energy shift in the position of the TiO₂ features (~0.5 eV) could be a result of changes in band bending^{20c} induced by the adsorbates (NO₃ and NO₂, see Figure 1). Heating from 200 to 400 K causes desorption of NO₂ from the surface, and there is a shift and decrease in the intensity of the NO_x features in Figure 2. These features are completely removed upon heating to 600 K. The photoemission results in Figures 1 and 2 indicate that NO₂ reacts with a TiO₂(110) surface to form stable NO₃ species with relatively minor amounts of NO₂ and N.

Polycrystalline powders of TiO₂ (rutile or anatase structures) were exposed to a moderate pressure of NO₂ (~450 Torr) at 300 K. Figure 3 displays typical XANES data at the N K-edge for these systems and two common standards (KNO₂, KNO₃) which show the electronic transitions within the NO₃ and NO₂

(37) Dines, T. J.; Rochester, C. H.; Ward, A. M. *J. Chem. Soc., Faraday Trans.* **1991**, *87*, 643 and references therein.

Figure 3. (Left) N K-edge XANES results for TiO_2 powders (anatase or rutile structures) exposed to NO_2 at 300 K. For comparison, we also include the results for two common standards: KNO_2 and KNO_3 . (Right) N K-edge spectra taken after exposing a powder of TiO_2 (rutile structure) to NO_2 (450 Torr, 15 min) at 300 K, followed by evacuation of the gas and heating in a vacuum to 400, 500, 600, and 700 K.

groups. In the spectrum for the pure nitrate, the intense resonance at a photon energy of ~ 407 eV corresponds to $1s \rightarrow 2a_2''(\pi)$ electronic transitions, whereas the broad features between 410 and 420 eV probably come from excitations into the $5a_1'$ and $5e'$ empty σ orbitals of NO_3 .⁷ In the case of the NO_2 salt, the first strong peak at ~ 403 eV corresponds to $1s \rightarrow 2b_1(\pi)$ electronic transitions, with the envelope from 407 to 417 eV probably resulting from excitations into $7a_1$ and $5b_2$ vacant σ orbitals of nitrogen dioxide.⁷ In Figure 3, the spectra for the TiO_2 powders exposed to nitrogen dioxide show strong resonances for NO_3 and a weak signal for NO_2 . Heating to higher temperatures led to removal of the features for chemisorbed NO_2 by 400 K, and NO_3 by 700 K. This is similar to the trends seen after adsorbing NO_2 on the $\text{TiO}_2(110)$ surface. Since polycrystalline powders of TiO_2 expose a substantial amount of Ti centers on their surfaces,^{13,20a} the lack of a strong signal for chemisorbed NO_2 in Figure 3 could be attributed³⁷ to a low reactivity of the Ti centers with NO_3 being formed by the interaction of NO_2 with O centers, reaction 1. A different interpretation will be presented below.

III.2. Bonding of NO_2 to $\text{TiO}_2(110)$ and Formation of NO_3 .

The bonding of NO_2 to the (110) face of titania in a rutile structure was studied using DF-GGA calculations. The TiO_2 -(110) surface was represented by a four-layer slab as shown in Figure 4, which was embedded in a three-dimensionally periodic supercell.^{22,24,25} A vacuum of 12 Å was placed on top of the slab in order to ensure negligible interactions between periodic images normal to the surface.^{22,24,27} Previous theoretical studies have shown that a three-layer periodic slab can reliably model adsorption reactions on a perfect $\text{TiO}_2(110)$ surface.^{22,25,38} In

our calculations, we added one more layer since we are also interested in examining the behavior of titania systems with vacancies on the surface and subsurface region (section III.4). The geometry optimization for bulk TiO_2 gave a rutile unit cell with $a = b = 4.64$ Å and $c = 2.97$ Å. These values are close to those derived from experimental measurements ($a = b = 4.59$ Å, $c = 2.96$ Å)³⁹ and other theoretical calculations.^{25,38b} In the slab calculations, the structural geometry of the first two layers was relaxed, while the other two layers were kept fixed in the geometry of bulk TiO_2 . For the perfect $\text{TiO}_2(110)$ surface, the 5-fold- and 6-fold-coordinated Ti ions moved in and out of plane by 0.15 and 0.11 Å, respectively. The bridging oxygens moved into the surface by 0.10 Å, and the in-plane oxygens moved out of the surface by 0.11 Å. These shifts in the atom positions agree well with those seen in other DF studies.^{25,38b} Most of them are also in good agreement with atomic shifts found in X-ray surface diffraction studies for $\text{TiO}_2(110)$,⁴⁰ the only exception being the shift for the bridging oxygens, where the experimental results give a movement of 0.27 Å toward the surface.

Before studying the adsorption of NO_2 on $\text{TiO}_2(110)$, we examined the adsorption of NO as a test case. The NO molecule ($\theta_{\text{NO}} = 0.25$ ML) was bonded to atoms in the bridging O rows (via N) or atoms in the Ti rows (via N or O). In agreement with previous infrared and DF-GGA studies,^{25a,41} we found that bonding to Ti via N was the most stable configuration. The calculated NO adsorption energy (11.6 kcal/mol) was close to

that determined from thermal desorption measurements (8.4 kcal/mol^{25a}).

Nitrogen dioxide was adsorbed on oxygen and metal centers of TiO₂(110) in the bonding configurations shown in Figure 5. The adsorption of NO₂ on atoms of the bridging O rows (η^1 -N on O, in our notation) produces NO₃-like species in accordance with reaction 1. On Ti sites, NO₂ can bond via nitrogen (η^1 -N) or the oxygens (η^2 -O,O). Both bonding configurations have been observed on transition metal surfaces.^{7,10,11} Table 1 displays adsorption geometries and bonding energies predicted by CASTEP for a NO₂ coverage of 0.25 ML on TiO₂(110). In our DF-GGA calculations, the geometries of the adsorbate and two slab layers near the surface were optimized. In contrast to the case of adsorbed NO, where bonding to Ti through the N end has been observed,^{25a,41} NO₂ prefers to bond to the oxide cations via the oxygens. An identical difference is found when comparing the forms of bonding of NO and NO₂ on metal surfaces.^{10,42} On Ti centers of TiO₂(110), NO₂ interacts more strongly than NO, with the electron density on adsorbed NO₂ ($q \approx -0.13e$) being larger than that on adsorbed NO ($q \approx +0.06e$). In the gas phase, NO and NO₂ have low-lying half-occupied electron-

acceptor orbitals:^{43,44} 2π in NO, and $6a_1$ in NO₂. The relative energy positions of the NO(2π) and NO₂($6a_1$) orbitals^{43,44} indicate that the dioxide should be the better electron acceptor and the more reactive species on TiO₂, in agreement with the trends seen in the DF calculations. In Table 1, it is clear that the bonding interactions of NO₂ with two Ti atoms are stronger than with O. Atoms in the bridging O rows of TiO₂(110) do not make strong bonds with NO₂, and the calculated adsorption energy (~ 15 kcal/mol) on these sites is not consistent with the large thermal stability observed for the nitrate species in the experimental results of Figure 1. As an alternative to reaction 1, we must find other viable route(s) for the formation of NO₃ on a TiO₂(110) surface.

A variant of reaction 1 involves the abstraction of bridging O from the oxide by NO₂ (adsorbed in a η^2 -O,O configuration) to form a bidentate nitrate species on the Ti sites. We calculated that this process is ~ 36 kcal/mol uphill with respect to η^2 -O,O chemisorbed NO₂ and, thus, can be ruled out as a route for obtaining a stable NO₃ species. Another possible pathway for the formation of NO₃ could be the adsorption of NO₂ in an η^2 -N,O configuration on O and Ti centers (see bottom of Figure 5). In this case, the calculated adsorption energy (18.4 kcal/mol) is comparable to that seen for an η^2 -O,O conformation on two Ti sites (21.3 kcal/mol), but not large enough to account for the high temperatures observed in Figure 1 for the decomposition of NO₃. Finally, NO₃ could be formed as a result

(44) (a) In the gas phase, NO and NO₂ are radical molecules with a low-lying half-occupied electron-acceptor orbital. The half-occupied orbital of NO₂, the $6a_1$ orbital, is ~ 2 eV more stable than the half-occupied orbital of NO, the 2π orbital.^{15,43} The experimental electron affinity of NO₂ is 1.7 eV larger than that of free NO.^{44b,c} (b) Refaey, K. Figure 6. N K-edge XANES spectra taken after exposing powders of MgO, CeO₂, Cr₂O₃, Fe₂O₃, CuO, and ZnO to NO₂ (~450 Torr, 15 min) at 300 K.

of the disproportionation of NO₂ on Ti sites:

We calculated an energy change of -8 kcal/mol (exothermic process) for this reaction when the formed NO₃ is bidentate on Ti sites ($\eta^2\text{-O}_2\text{O}$ bonding) and has a coverage of 0.25 ML. To decompose the produced nitrate

one has to put 41 kcal/mol of energy into the system. This value is consistent with the elevated temperatures seen experimentally for the decomposition of NO₃ on TiO₂(110).

The theoretical results described in this section show that the $\text{Ti} \leftrightarrow \text{NO}_2$ interactions on TiO₂(110) are strong, and as a result of them the cations can get covered with nitrate. This unexpected mechanism for NO₃ formation is consistent with the photoemission data in Figure 1, where chemisorbed NO₂ is present at 100 K and its signal decreases upon heating to 200 K with simultaneous appearance of NO₃. In addition, reaction 2 explains the lack of an intense signal for chemisorbed NO₂ in the N K-edge XANES spectra of Figure 3. The metal centers exposed on the surfaces of polycrystalline powders of TiO₂ are more reactive than those in a TiO₂(110) surface, and upon interaction with NO₂ probably react fast, forming NO₃ groups. Reaction 2 must be taken into consideration when using oxides in DeNO_x operations. Figure 6 shows XANES spectra for the adsorption of NO₂ on a series of polycrystalline powders. All these oxides contain metal centers in their surfaces,^{13,20a} and the weak or missing signal for chemisorbed NO₂ does not imply a lack of reactivity of these metal centers toward NO₂. Such a behavior will not be compatible with the fact that the metal centers in these oxides interact well with molecules that are less chemically active than NO₂.^{13,20} It is much more likely that

Figure 7. Ti 2p spectra taken before and after adsorbing NO₂ on an O-vacancy-rich TiO_{2-x}(110) surface at 300 K. The spectrum for the clean TiO_{2-x}(110) surface at the bottom was curve-fitted using a convolution of Gaussian and Lorentzian functions.^{22,23} A photon energy of 625 eV was used to acquire these spectra.

in all these oxide systems the surface metal centers get covered with nitrate upon exposure to NO₂. Support for this idea is provided by the experiments in the following section for NO₂ on O-vacancy-rich titania.

III.3. Reaction of NO₂ with Defect-Rich TiO_{2-x}(110). In general, an important issue in oxide catalysis is the role of surface defects in determining the activity and selectivity of the catalyst.^{19,20,25a,43,45} It is well known how to generate O vacancies in the TiO₂(110) substrate.^{13,21,46} These O vacancies are distributed from the surface to the bulk of the material and lead to Ti centers with relatively low formal oxidation states ($\leq 3+$). We found that NO₂ is very efficient for the reoxidation of these Ti centers. The type of oxide surface used in the experiments of Figures 1 and 2 contains O vacancies with a density of ~7%.^{21,23} For these systems, the associated Ti³⁺ centers completely transform into Ti⁴⁺ upon reaction with NO₂ at 300 K. A more extreme case is shown in Figure 7. A titania system rich in O vacancies and defects was produced by Ne⁺ bombardment and subsequent annealing at 950 K. The resulting Ti 2p spectrum (bottom of Figure 7) exhibited very broad features. Curve-fitting indicates that the complex Ti 2p features arise from the convolution of three doublets, which correspond to Ti⁴⁺, Ti³⁺, and a Ti species in an even lower oxidation state (Ti ^{$\delta+$} , $\delta < 3$). After a dose of 10 L of NO₂ at 300 K, only a well-defined doublet for Ti⁴⁺ was observed. The adsorbate was able to eliminate all the Ti³⁺ and Ti ^{$\delta+$} sites in the surface and subsurface region probed by photoemission (2–3 layers). Since NO₂ is a bulky molecule, this result implies that O vacancies and related defects migrate toward the oxide surface in the presence of NO₂. This interesting phenomenon will be studied in more detail in section III.4 using DF calculations.

Oxygen vacancies drastically change the chemistry of NO₂ on a titania surface. Figure 8 displays N 1s spectra taken after dosing NO₂ at 300 K to a TiO_{2-x}(110) system characterized by broad Ti 2p features such as those seen in Figure 7. Initially this defect-rich system is very reactive, and for the first dose of NO₂ a clear peak is observed near 399 eV for atomic N⁴³ produced by full decomposition of the adsorbate:

(45) Kolmakov, A.; Stultz, J.; Goodman, D. W. *J. Chem. Phys.* **2000**, *113*, 7564.

Figure 8. N 1s spectra acquired after several doses of NO₂ (0.2, 0.5, 1.0, 2.0, and 5.0 L) to an O-vacancy-rich TiO_{2-x}(110) surface at 300 K. The electrons were excited using a photon energy of 500 eV.

The features for atomic N disappear upon additional dosing of NO₂, probably due to oxidation of the surface by the reaction:

Reaction 5a is known to be very effective for the oxidation of metals.^{10,11c} The fact that oxides are more stable than nitrides⁴⁷ favors the replacement of Ti–N bonds with Ti–O bonds. At medium size doses of NO₂, a peak is seen at ~402.5 eV in Figure 8. Such position is between those expected for chemisorbed NO (401–402 eV) and NO₂ (403–404 eV).^{15,16,43} At the end, after a big dose of NO₂, there is a large content of oxygen in the system (i.e., the oxygen vacancies have been eliminated), and only NO₃ is observed on the surface. The same product was found for the interaction of NO₂ with a TiO₂(110) surface (see Figure 1). The photoemission results in Figures 7 and 8 give a good indication of what may happen when polycrystalline powders of oxides are exposed to moderate pressures of NO₂. Any metal center that is present in the surface of the powder and has a relatively small coordination number (or low oxidation state) eventually will get oxidized or nitrated.

III.4. Bonding of NO₂ to TiO_{2-x}(110). To model a TiO_{2-x}(110) surface with O vacancies, we used a four-layer periodic slab with atoms missing from the bridging oxygen rows in the first layer (center of Figure 4).^{22,25a} This is the most common position observed for O vacancies when their number is

Figure 9. Density functional results for the density of states (DOS) of the occupied bands in TiO₂(110) and a TiO_{2-x}(110) system with O vacancies in the surface. The zero of energy in the figure is not the vacuum level.²⁴

moderate or low.^{13,21} In many situations it is unlikely that O vacancies in TiO₂ will assume a periodic array such as that shown in Figure 4, but our model represents well the electronic perturbations associated with the formation of O vacancies (see below). As in the case of the perfect TiO₂(110) slab, the structural geometry of the first two layers in the TiO_{2-x}(110) slab was relaxed while the bottom two layers were kept fixed in the geometry of bulk titania. There was a substantial relaxation in the region near a missing oxygen with the adjacent Ti atoms moving downward and sideways (0.16–0.19 Å) to strengthen their bonds with the remaining oxygens. Figure 9 displays the calculated (DF-GGA) density of states for the occupied bands in the perfect TiO₂(110) slab (bottom panel) and in the TiO_{2-x}(110) slab with O vacancies in the surface

^a Positive values denote an exothermic process.^{22,26} ^b θ_{NO₂} = 0.25 ML. ^c The numbers in parentheses are for the O bonded to the Ti rows (see Figure 10).

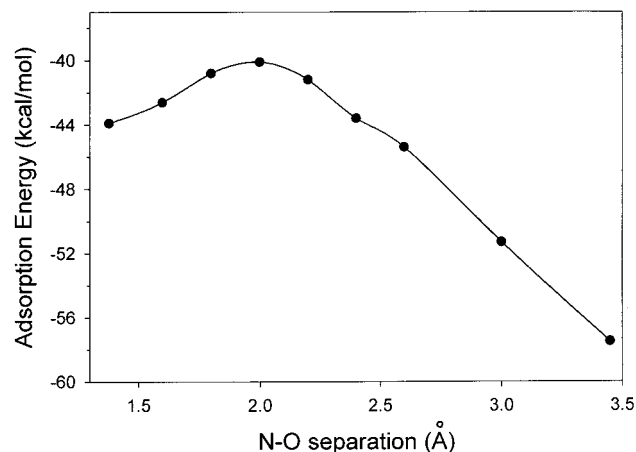

Figure 11. Energy path for the dissociative adsorption of NO₂ on a TiO_{2-x}(110) system with surface vacancies. The precursor for dissociation involves an η²-O,O coordination of NO₂ above an O vacancy and an atom in a Ti row. In the final state, the O vacancy has been eliminated, and a NO molecule is bonded to an atom in a Ti row via its N end. Ti atoms are represented by dark spheres, whereas gray spheres correspond to O atoms.

(top panel). The valence band in TiO₂(110) contains states of O 2p and Ti 3d character. Since the Ti–O bonds are not fully ionic and have a large degree of covalent character,^{22,38a,38b} TiO₂ is best described as an ionocovalent oxide.^{38b} The introduction of O vacancies in the TiO₂(110) surface generates a new occupied state that appears ~1.6 eV above the top of the {O 2p + Ti 3d} band and has Ti 3d character. This state is observed in experiments of valence photoemission^{13,48} and is frequently attributed to Ti³⁺ ions.⁴⁸ Our DF calculations indicate that this vacancy state in TiO_{2-x}(110) plays a predominant role in the bonding and surface chemistry of NO₂.

The NO₂ was bonded to the TiO_{2-x}(110) surface in the configurations shown in Figure 10. They involve coordination to two atoms in a Ti row (η²-O,O on Ti row), or direct bonding on O vacancies via one O (η²-O,O on vac,Ti) or N (η²-N,O on vac,Ti) of the molecule. Table 2 lists structural parameters and adsorption energies obtained after relaxing the geometry of the

Figure 12. NO₂-induced migration of O vacancies. Initially, NO₂ is adsorbed on the Ti rows and O vacancies are located in the subsurface or bulk region. In the final state, the O vacancies have moved to the surface and half of them are “covered” by O atoms of NO₂. In the scheme, only three of the four layers in the slab models are shown. Ti atoms are represented by dark spheres, whereas gray spheres correspond to O atoms.

adsorbate (θ_{NO₂} = 0.25 ML) and first two layers in our slab model. In the presence of O vacancies, the bonding energy of NO₂ on two atoms of a Ti row (24.9 kcal/mol) is larger than that found on a perfect TiO₂(110) surface (21.3 kcal/mol), but not as large as those seen for adsorption of the molecule above O vacancies (36–44 kcal/mol). In these adsorption sites, the underlying Ti atoms interact very well with the LUMO of the NO₂ molecule (6a₁ orbital^{7,43}), with a substantial Ti(3d) → NO₂-(6a₁) electron transfer and a weakening of the N–O bonds that facilitates dissociation of the adsorbate.

The most stable bonding configuration in Figure 10 corresponds to NO₂ adsorbed with one of its O atoms above an oxygen vacancy and the other O near an atom in a Ti row. This configuration is characterized by one very large N–O bond distance (1.38 Å) and is an ideal precursor for dissociation of the NO₂ molecule. Figure 11 shows calculated energy changes along a possible reaction path for the

reaction on a TiO_{2-x}(110) surface. In the final state, the produced NO fragment is adsorbed on a Ti row, and an O vacancy has been eliminated. To obtain the curve in Figure 11, for each N–O separation, we relaxed all the other structural parameters of the

(48) Sadeghi, H. R.; Henrich, V. E. *J. Catal.* **1988**, *109*, 1 and references therein.

surface. Overall, the NO₂ dissociation process on an O vacancy is exothermic ($\Delta E = -13.6$ kcal/mol), with a small activation energy barrier (3.8 kcal/mol). The same reaction on the Ti rows of a perfect TiO₂(110) surface is an endothermic process ($\Delta E = +4.3$ kcal/mol). If the concentration of O vacancies in the oxide surface is large, the NO produced by reaction 6 could be decomposed into atomic N and O. If no O vacancies are present, the NO, which is weakly bound to the Ti sites (see above), could desorb at temperatures below 300 K or be displaced by an NO₂ molecule. The DF calculations indicate that reactions 2 and 6 are the key to the chemistry of NO₂ on TiO₂(110). First, reaction 6 eliminates O vacancies from the oxide surface. This is then followed by the formation of NO₃ on the Ti rows by reaction 2.

The photoemission experiments in section III.1 show that NO₂ can oxidize Ti³⁺ sites located in the subsurface or bulk regions of titania. Our DF results indicate that this phenomenon reflects changes induced by NO₂ on the relative stability of O vacancies in the surface versus subsurface regions. After cleaning/preparing a titania sample, one obtains a distribution of O vacancies from the surface to the bulk of the system.^{13,21,46} Using the two slab models shown at the center and bottom of Figure 4, we compared the thermochemical stability of O vacancies in the surface and subsurface regions of TiO₂(110). After structural relaxation of the top two layers in each slab, the DF-GGA calculations give a small difference in stability (<3 kcal/mol) that is within the accuracy of the theoretical method.^{25a,33} On the other hand, when NO₂ is present on the surface, the migration of O vacancies from the subsurface region to the surface (see Figure 12) is a highly exothermic process ($\Delta E = -25.3$ kcal/mol). *Such migration is a requirement for the dissociation of adsorbed NO₂*, and eventually leads to oxidation or elimination of Ti³⁺ centers. Furthermore, DF calculations indicate that adsorbed NO and N₂O also facilitate the movement of oxygen vacancies from the bulk to the surface of titania from a thermochemical viewpoint. In the case of N₂O adsorption, we have verified this prediction in experiments similar to those seen in Figure 7. Thus, in DeNOx operations, not only the

surface properties of an oxide are important. In addition, the subsurface composition of the sorbent/catalyst can determine the trapping of NO_x species and N–O bond cleavage.

IV. Conclusions

The main product of the adsorption of NO₂ on TiO₂(110) is surface nitrate with a small amount of chemisorbed NO₂. A similar result is obtained after the reaction of NO₂ with polycrystalline powders of TiO₂ or other oxides (MgO, CeO₂, Cr₂O₃, Fe₂O₃, CuO, ZnO). This trend, however, does not imply that the metal centers of the oxides are unreactive toward NO₂. Photoemission data and DF calculations indicate that the surface nitrate forms through the disproportionation of NO₂ on Ti sites ($2\text{NO}_{2,\text{ads}} \rightarrow \text{NO}_{3,\text{ads}} + \text{NO}_{\text{gas}}$) rather than direct adsorption of NO₂ on O centers of titania. Ti^{δ+} ($\delta \leq 3$) centers present on TiO_{2-x}(110) surfaces react readily with NO₂ and eventually all become oxidized or covered with nitrate. The interactions between NO₂ and O vacancies of TiO₂(110) are complex. Electronic states associated with O vacancies interact very well with the LUMO of NO₂, with a substantial Ti(3d) \rightarrow NO₂(6a₁) electron transfer and a weakening of the N–O bonds that favors dissociation of the molecule. This changes the chemistry of NO₂ on TiO₂(110). At the same time, the adsorbed NO₂ affects the thermochemical stability of O vacancies, facilitating their migration from the bulk to the surface of titania. The behavior of the NO₂/titania system illustrates the importance of surface *and* subsurface defects when dealing with DeNOx reactions on oxides.
