Received July 12, 1996. Revised Manuscript Received December 3, 1996[®]

Abstract: Ab initio MO calculations at the MP2/6-311G** level of theory show that the thiosulfoxide H₂SS is 143 kJ mol⁻¹ less stable than the disulfane HSSH, separated by an activation barrier of 210 kJ mol⁻¹. Using much higher levels of theory, these results are only slightly changed, proving the suitability of the economical MP2/6-311G** scheme for the present purpose. At the same level Me₂SS is 84 kJ mol⁻¹ less stable than MeSSMe, with the transition state lying 340 kJ mol⁻¹ above MeSSMe. Thermal isomerization of HSSH or MeSSMe can therefore be excluded, and H₂SS and Me₂SS should be kinetically stable toward unimolecular isomerization at low temperatures. Vibrational wavenumbers for H₂SS and Me₂SS are given. The allyl methyl thiosulfoxide MeAllSS is 83 kJ mol⁻¹ less stable than the disulfane MeSSAll, but isomerization of the latter requires only 110 kJ mol⁻¹. The corresponding RSSR and R₂SS structures for R = Pr and All have been calculated at the HF/6-31G* level. The bimolecular decomposition of dimethyl thiosulfoxide to dimethyl sulfide and S₂ is exothermic but spin-forbidden in the case of triplet S₂, and endothermic but spin-allowed when singlet S₂ is formed. The reactions of Me₂SS with sulfur molecules S_x (x > 2) to give Me₂S and S_{x+1} are exothermic.

Introduction

Organic thiosulfoxides R₂SS have never been isolated or directly observed, but numerous times their role as reaction intermediates has been discussed.³ On the other hand, compounds which formally contain SS double bonds have been known for quite some time: Thiotionyl fluoride F₂S=S (1), a colorless gas, is more stable thermodynamically than the isomeric difluorodisulfane FSSF (2).⁴ Disulfur monoxide S=S=O (3) is stable for several days at 20 °C.⁵ The cyclic thiosulfite RO-S(=S)-OR (4) with R = cyclohexylidene is stable at 20 °C,⁶ and several stable thiosulfinylamines RN=S=S (5) have been prepared.^{3a} The molecular structures of the species 1–5 are known from either microwave spectroscopy (1–3) or X-ray crystallography (4, 5), and SS bond distances in the range 186–191 pm have been observed. Since the distance of SS single bonds⁷ as in S₈ is ca. 205 pm, the species 1–5 may be considered as formally containing SS double bonds.

It is interesting to note that the SiSi double bonds in disilenes R₂Si=SiR₂⁸ and the PP double bonds in diphosphenes RP=PR⁹ are also ca. 7–10% shorter than the single bonds in the corresponding saturated compounds. It was the aim of this work to find out whether this also holds for organic thiosulfoxides R₂SS versus disulfanes RSSR and for their parent compounds H₂SS and HSSH. In addition, we have calculated for the first time the structures and energies of the transition states for the interconversion of RSSR into R₂SS and vice versa. The relative energies of the two isomers R-S-S-R (6) and R₂S=S (7) have so far only been determined for R = H, OH, and SH. According to an ab initio MO calculation at the MP2/6-311G**/HF/6-311G** + ZPE level of theory, the acyclic parent compound of 4, HO-S(=S)-OH is only 14 kJ mol⁻¹ less stable than the unbranched isomer HOSSOH.¹⁰ At the MP2/6-31G*/HF/4-31G* level the thiosulfoxides H₂SS and (HS)₂SS have been found to be 141 and 132 kJ mol⁻¹ less stable than the corresponding sulfanes HSSH and HSSSSH, respectively.^{11,12}

To determine the structures and energies of organic thiosulfoxides as well as the activation energies for their formation from disulfanes, we have carried out extensive ab initio MO

calculations on (CH₃)₂S₂, (C₃H₇)₂S₂, (CH₃)(C₃H₅)S₂, (C₃H₅)₂S₂, and—for comparison—on H₂S₂ (C₃H₅ = 3-allyl).

Methods of Calculation

All geometries were optimized at the Hartree–Fock and, with the exception of the Pr₂S₂ and All₂S₂, also at the valence electron correlated MP2 level of theory, employing 6-31G* and 6-311G** one particle basis sets. The force constant matrices and the harmonic frequencies were computed analytically for each stationary point to characterize it as a minimum or a saddle point and to provide predictions for the vibrational spectra. These calculations were performed at the MP2/6-311G** (H₂S₂, Me₂S₂), the HF/6-311G** (MeAllS₂), and the HF/6-31G* (Pr₂S₂, All₂S₂) levels of theory. The HF and MP2 wavenumbers were uniformly scaled by factors of 0.8929 and 0.9427, respectively, while the corresponding zero point energies (ZPE) were scaled by 0.9135 (HF) and 0.9646 (MP2).¹³ For assessing the accuracy of the structures and in particular the relative energies that can be expected from the above approach based on single-reference-based MP2 calculations, we performed additional calculations on the H₂S₂ potential energy surface employing more sophisticated theoretical approaches. The geometries were determined at the complete active space SCF (CASSCF)¹⁴ level where all 14 valence electrons were distributed in the 10 orbitals originating from the 3s and 3p atomic orbitals of sulfur and the 1s hydrogen orbital. A generally contracted basis set of the atomic natural orbital (ANO)¹⁵ type of (7s3p)/[3s2p] and (13s10p4d)/[5s4p3d] quality was employed for hydrogen and sulfur, respectively. This set will be denoted as ANO-S. For subsequent energy calculations a considerably larger basis set (H, (8s4p3d)/[3s2p1d]; S, (17s12p5d4f)/[6s5p4d3f] (ANO-L)) was selected. Energies were obtained at second-order multireference perturbation theory based on a CASSCF wave function (CASPT2),¹⁶ by full fourth-order Møller–Plesset perturbation theory (MP4sdq) and by coupled cluster calculations with single and double excitations and a perturbative estimate of the triple contributions (CCSD(T)).¹⁷ Thus, both dynamic as well as static electron correlation effects are well covered by these methods. Scalar relativistic effects were included in the CASSCF/CASPT2 calculations through the Douglas–Kroll operator.¹⁸ The programs Gaussian 94,¹⁹ MOLCAS-

3,²⁰ GAMESS,²¹ and MOLPRO 96²² as installed on IBM RS/6000 workstations or a CRAY-J90 computer were used.

Results and Discussion

H₂S₂. The relative energies of the three relevant species, i.e., HSSH, H₂SS, and the saddle point connecting these two minima, are collected in Table 1.²³ The energy difference (with ZPE corrections computed at MP2/6-311G**) between the two stable isomers amounts to 113, 115, and 117 kJ mol⁻¹ using the ANO-L basis and the CASPT2, MP4, and CCSD(T) approaches, respectively. If instead the smaller 6-311G** or 6-31G* basis sets combined with the MP2 or MP4 treatment are employed, HSSH is predicted to be more stable than H₂SS by 141–145 kJ mol⁻¹. That this difference is indeed a pure basis set effect can be seen by comparing the MP4 results obtained with the 6-311G** and the ANO-L basis set, which amount to 143 and 115 kJ mol⁻¹. As expected, the scalar relativistic effects have hardly any impact on the relative stabilities. The good agreement between the results obtained by three different treatments of electron correlation (CCSD(T), MP4, and CASPT2) demonstrate that this system is “well-behaved” and can be treated with single-determinant-based methods, such as MP2. This is further corroborated by the very small τ_1 diagnostic in the CCSD, which is well below the critical value of 0.02¹⁷ (HSSH, τ_1 = 0.004; H₂SS, τ_1 = 0.006) and by the CASSCF wave function, which is strongly dominated by the HF reference configuration.

The geometries and dipole moments as calculated at the MP2/6-311G** level of theory are shown in Table 2 together with the structural data obtained at the CASSCF level with the ANO-S basis set. Also included in Table 2 is the experimental geometry of HSSH as determined by microwave spectroscopy.^{24,25} HSSH adopts a helical structure of C₂ symmetry while H₂SS is of C_s symmetry (Figure 1). The MP2/6-311G** geometry of HSSH is in slightly better agreement with the experimental structure than the one obtained at the CASSCF/ANO-S level. In particular the SS bond is overestimated by 2.6 and 5.6 pm at the two levels of theory, respectively. Also the SS bond in H₂SS is probably somewhat overestimated in the calculations (here both methods give almost identical results

^a Data given in brackets refer to calculations at the CASSCF/ANO-S level, while the experimental results for HSSH²⁴ are given in parentheses. For numbering of atoms see Figure 1. ^b 1 D = 3.336×10^{-30} C m.

**Figure 1.** Structures of HSSH, H₂SS, and the transition state (TS) of the interconversion reaction.

of 201.8 and 201.7 pm, respectively), and it can be assumed that the true value of $d(\text{SS})$ for this molecule should be 199 pm. As expected, the dipole moment of H₂SS is much larger (5.39 D at MP2/6-311G** and 4.00 D at CASSCF/ANO-L) than that of HSSH (1.56 and 1.16 D at MP2/6-311G** and CASSCF/ANO-L, respectively). The Mulliken charges on S1 and S2 obtained with the 6-311G** basis amount to +0.34 and -0.49 in H₂SS and to only -0.07 in HSSH.

For the energetically less favorable isomer H₂SS to be experimentally observable, a sizable barrier must prevent the rearrangement back to the more stable form HSSH. Therefore, we have localized the saddle point for the hydrogen migration connecting the two isomers, whose energetical and geometrical data are also included in Tables 1 and 2, respectively. This saddle point is rather high in energy: Including ZPE corrections, its energy computed at MP2/6-311G** is 210 and 67 kJ mol⁻¹ above HSSH and H₂SS, respectively. If instead the more elaborate CCSD(T) and CASPT2 approaches combined with the ANO-L basis set are employed, only slightly different barrier heights of 195 kJ mol⁻¹ (CCSD(T) and CASPT2) with respect to HSSH and 78 (CCSD(T)) and 82 (CASPT2) kJ mol⁻¹ relative to H₂SS are obtained. This, together with the small τ_1 diagnostic of 0.004, indicates that also the saddle point does not require a multireference treatment. Rather, the differences between the MP2/6-311G** data and the results obtained at higher levels of theory are mainly caused by the more flexible one-particle basis set used in the latter as documented by the barrier height of also 196 kJ mol⁻¹ computed with the large ANO basis set in the MP2 scheme (the corresponding MP4 number amounts to 194 kJ mol⁻¹). Scalar relativistic effects have an only negligible influence on these data. Hence, it can safely be concluded that the simple MP2 electron correlation treatment is sufficient for a description of the minima and saddle points of the molecules studied in the following. For the present system, the computational data suggest that once H₂SS has been generated at not too high temperatures it should be possible to detect this species,

e.g., by vibrational spectroscopy. To assist an experimental identification, the harmonic wavenumbers of the six fundamental vibrations of H₂SS as well as their relative infrared intensities are given in Table 3.

Me₂SS. The calculated relative energies of MeSSMe²⁶ and Me₂SS assuming C₂ and C_s symmetry, respectively, are given in Table 1 while the geometrical parameters and dipole moments are compiled in Table 4. The experimental structure of MeSSMe²⁷ is also given in Table 4. Including ZPE corrections the thiosulfoxide is only 84 kJ mol⁻¹ less stable than the disulfane. This energy difference is much smaller than in the case of H₂SS/HSSH (143 kJ mol⁻¹) which may be rationalized as follows. The SS bonds of the thiosulfoxides H₂SS and Me₂SS are highly polar. The charge difference between S1 and S2 is 0.83 e in H₂SS and 0.92 e in Me₂SS; i.e., these bonds are "semipolar". The positive charge on S1 of H₂SS seems to weaken the two adjacent SH bonds, the distances of which are 1.5 pm larger than in HSSH. In contrast, the CS bonds in Me₂SS are 0.6 pm shorter than those in MeSSMe, obviously as a result of the large charge difference of 0.9 e between S1 and the carbon atoms. Thus, the strengthening of the CS bonds of Me₂SS compared to MeSSMe is a result of the negative charge of the carbon atoms (-0.4 e) whereas the hydrogen atoms of HSSH and H₂SS are positively charged (+0.1 e). It therefore seems that the gain in CS bond energy on isomerization of MeSSMe to Me₂SS is at least partly responsible for the relatively low energy needed for this process.

The large negative charge on the terminal sulfur atom of Me₂SS raises the question whether there are intramolecular S...H hydrogen bonds. However, the shortest SH contact in Me₂SS

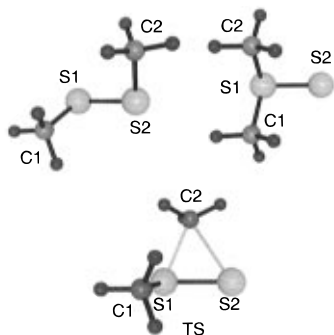

Figure 2. Structures of MeSSMe, Me₂SS, and the transition state (TS) for the interconversion reaction.

is 305.6 pm which is larger than the van der Waals distance. The absence of S...H bonds also holds for Pr₂SS, MeAl₂SS, and Al₂SS discussed below.

The structure of the transition state (TS) for the isomerization of MeSSMe and Me₂SS is shown in Figure 2; the geometrical parameters are listed in Table 4 while the energies at various levels of theory are given in Table 1. TS is characterized by a triangular arrangement of the two sulfur atoms and one methyl carbon atom. Within this triangle all bond lengths are considerably larger than in MeSSMe. These weak bonds must be the main reason that the transition state energy is 340 kJ mol⁻¹ higher than the energy of MeSSMe.

The extremely high energy of TS raises doubts whether the isomerization of MeSSMe to Me₂SS in fact proceeds via an intramolecular methyl shift. An alternative pathway would be the homolysis of one CS bond followed by a migration of the CH₃ radical to the second sulfur atom and formation of a new CS bond, enhancing the coordination number of that sulfur atom from 2 to 3. The bond dissociation energies of MeSSMe as given by Benson²⁸ are $D(\text{H}_3\text{CS}-\text{SCH}_3) = 310$ and $D(\text{H}_3\text{C}-\text{SSCH}_3) = 238$ kJ mol⁻¹. From these data it follows that the isomerization of MeSSMe to Me₂SS probably takes place by a homolytic dissociation mechanism. Even the calculated activation energy for the reverse reaction Me₂SS → MeSSMe (256 kJ mol⁻¹) is higher than $D(\text{H}_3\text{C}-\text{SSCH}_3)$. Therefore, the homolytic pathway may also be more favorable here. Once Me₂SS has been formed it is expected to be quite stable kinetically due to these high activation barriers. To detect Me₂SS, for instance by matrix isolation experiments, the vibrational wavenumbers listed in Table 3 may be helpful. The SS stretching vibration at 496 cm⁻¹ has the highest infrared intensity.

Strausz et al.^{3b} proposed that Me₂SS is formed in the reaction of sulfur atoms with gaseous Me₂S. Depending on the electronic state of the sulfur atoms (³P or ¹D; generated by photolysis of COS) the thiosulfoxide is formed primarily in an electronically excited triplet state (T₁) or in a vibrationally excited singlet state (S₀). Part of these molecules transform into MeSSMe by an unknown mechanism, but in addition elemental sulfur is formed which was explained by the following bimolecular reactions:^{3b}

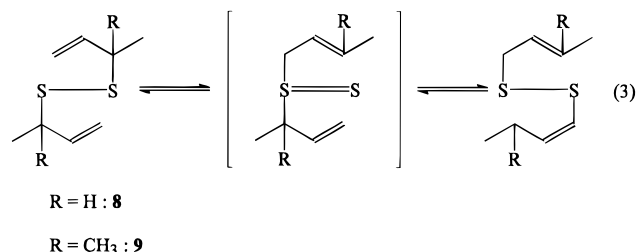

These processes will be discussed below.

Pr₂S₂ and Al₂S₂. The propyl derivatives were investigated to check whether the results obtained for MeSSMe and Me₂SS and in particular the difference from the HSSH/H₂SS pair would

persist if the alkyl chain is enlarged. The related allyl compounds have been studied experimentally, and allyl thiosulfoxides have been postulated as intermediates (see below), but no structures are known. Due to the size of these species computations are limited to the HF/6-31G* level. At the MP2 level only single-point energies of PrSSPr, Al₂SSAl, and their isomeric thiosulfoxides were obtained,²³ and relative energies are given in Table 1; selected geometrical parameters are listed in Table 5 while the structures are shown in Figure 3. The thiosulfoxides Pr₂SS and Al₂SS are 74 and 78 kJ mol⁻¹ less stable than the related disulfanes. These values are comparable to the 82 kJ mol⁻¹ calculated at the same level for Me₂SS versus MeSSMe.

The most stable conformations of PrSSPr and Al₂SSAl are of C₂ symmetry, but the two thiosulfoxides are of C₁ rather than C_s symmetry. The highly polar nature of the semipolar SS bond results in dipole moments of the thiosulfoxides which are more than twice as large as those of the related disulfanes. Thiosulfoxides should therefore be stabilized by polar environments.

Diallyldisulfane has been isolated from various *Allium* species, and its reactions including thiosulfoxide formation are believed to be responsible for the formation of various derivatives on heat treatment of garlic oil.²⁹ From the study of the two diallyldisulfanes **8** and **9** comes the only experimental data available in the literature regarding the activation energy of the sigmatropic rearrangement shown in eq 3.

From the temperature dependence of the reaction rate the activation energy in benzene solution has been calculated as 83(4) kJ mol⁻¹ for R = H and as 78(4) kJ mol⁻¹ for R = CH₃.³⁰ These low values together with other chemical evidence³¹ have been interpreted as indication for the intermediacy of thiosulfoxides in various thermal reactions of diallyldisulfane(s). The sigmatropic rearrangement observed in reaction 3 obviously proceeds via a transition state totally different from the one shown in Figure 2 for Me₂S₂. On the basis of the first-order kinetics and the negative entropy of activation (ΔS^\ddagger ca. -9 J mol⁻¹ K⁻¹),²³ a structure with a five-membered C₃S₂ ring has been proposed. We have calculated the geometry and energy of this transition state (TS) at the same level of theory. The results are given in Tables 1 and 5, and the geometry is shown in Figure 3. The energy of TS is 111 kJ mol⁻¹ higher than that of Al₂SSAl and 33 kJ mol⁻¹ higher than the energy of Al₂SS. The cyclic structure of TS fits the above-mentioned expectations: one allyl group and the two sulfur atoms form an asymmetric puckered ring with a short SS bond (199.1 pm), two CC bonds of similar length (136.7 and 139.3 pm), and two very different and long CS bonds (237.6 and 261.0 pm).

^a For numbering of atoms see Figure 3.**Figure 3.** Structures of PrSSPr, Pr₂SS, AllSSAll, All₂SS, and the transition state (TS) for the interconversion reaction (All₂S₂).

The experimental activation energies for the forward reaction (3) of **8** and **9** (80 ± 3 kJ mol⁻¹ at 24 °C) are smaller than the calculated energy of TS relative to the energy of AllSSAll (111 kJ mol⁻¹). Even if the thermal energy at 298 K is taken into account, the relative energy of TS is still 106 kJ mol⁻¹. It therefore seems that the transition state is stabilized by interaction with the solvent. To check whether a higher level of theory would result in a lower relative energy of the transition state, we have investigated the thiosulfoxide formation from allylmethylthiylsulfane, which due to its smaller molecular size can be economically calculated at a higher level.

MeAllS₂. The structures of MeSSAll and MeAllSS, optimized at the MP2/6-311G** level of theory, are presented in Figure 4; selected geometrical parameters are compiled in Table 6. The relative energies given in Table 1 are in line with the findings for the dimethyl and diallyl species, the thiosulfoxide MeAllSS being 83 kJ mol⁻¹ less stable than the disulfane. Two transition states have been found (see Figure 4). The structure of TS₁ is similar to that of TS(Me): The allyl group faces the disulfane unit of the CH₃SS fragment with only one carbon atom (C2). The atoms C2, S1, and S2 define an unsymmetrical triangle in which the SS bond (214.7 pm) forms the shortest and the C2S2 bond the longest edge (242.7 pm). The energy of TS₁ relative to MeSSAll is 298 kJ mol⁻¹ (Table 1), slightly smaller than the relative energy of TS(Me) = 340 kJ mol⁻¹ but

**Figure 4.** Structures of MeSSAll, MeAllSS, and the transition states of the interconversion reaction. The energy of TS₁ is much higher than the energy of the cyclic TS₂.**Table 6.** Selected Bond Distances d (pm), Bond Angles α (deg), and Torsion Angles τ (deg), and Dipole Moments μ (D) of Allylmethylthiylsulfane, Its Thiosulfoxide, and of Two Transition States (TS) Calculated at the MP2/6-311G** Level^a

^a For numbering of atoms see Figure 3.

still larger than the CS bond dissociation energy (see Me₂S₂). The second transition state (TS₂) is 110 kJ mol⁻¹ less stable than MeSSAll and corresponds to TS of All₂S₂ (see above). While the relative energy of TS₂ is practically identical to the energy of TS(All), the geometry is significantly different. The SS distance of 196.0 pm is even smaller than in the thiosulfoxide (200.0 pm). The allyl group is connected to the disulfane unit through the terminal carbon atoms C2 and C4, forming a nonplanar five-membered heterocycle. However, the distance

C4–S1 (215.4 pm) is much smaller than C2–S2 (265.3 pm). In other words, the original bond All–S of MeSSAll has almost dissolved while the new CS bond is stronger than in the thiosulfoxide. As a consequence, the two CC bonds of the allyl group are of different length (C2–C3 = 136.9, C3–C4 = 142.3 pm) but have changed bond order compared with the disulfane MeSSAll (C2–C3 = 149.7, C3–C4 = 134.0 pm). The torsion angle C2SSC4 is only 3.8°.

Reactions of H₂SS and Me₂SS. Benson²⁸ has estimated the SS bond dissociation energies of H₂SS and Me₂SS from the enthalpies of formation ΔH° (kJ mol⁻¹ at 298 K) of sulfur atoms (³P; 277.6), H₂S (-20.5), Me₂S (-37.3), HSSH (15.9), and MeSSMe (-24.3) and from an estimate of the activation energy of the reaction of RSSAll with Ph₃P which results in RSAll and Ph₃PS.²⁴ The SS bond dissociation energies (*D*) derived are 214 ± 29 kJ mol⁻¹ for H₂SS and 222 ± 17 kJ mol⁻¹ for Me₂SS. Our results allow a more accurate calculation of these energies from the above ΔH° values and the relative energies of H₂SS and Me₂SS at 298 K. Taking the thermal energies into account, H₂SS is 144 kJ mol⁻¹ less stable than HSSH which leads to a reaction enthalpy ΔH°_{298} of 97 kJ mol⁻¹ for the reaction H₂SS → H₂S + S (³P), 117 kJ mol⁻¹ less than estimated previously.²⁸ In an analogous manner the reaction enthalpy for the dissociation of the SS bond of Me₂SS at 298 K is calculated as 181 kJ mol⁻¹, in reasonable agreement with Benson's estimate. The enthalpies of formation ΔH°_{298} (ideal gas) are calculated from our data and from the values for gaseous HSSH and MeSSMe as 160 kJ mol⁻¹ for H₂SS and 60 kJ mol⁻¹ for Me₂SS.

The decomposition of Me₂SS according to eq 1 was mentioned earlier. With S₂ molecules in the ³Σ_g⁻ ground state this reaction is spin-forbidden but exothermic by -31 kJ mol⁻¹ (calculated using the enthalpy of formation of S₂ as 128.5 kJ mol⁻¹ at 298 K²⁸). The spin-allowed reaction to give S₂ (¹Δ_g)³² is endothermic by 37 kJ mol⁻¹. The reaction of Me₂SS with S₂ (³Σ_g⁻) to give Me₂S and S₃ (eq 2) is spin-forbidden since the ground state of S₃ (and of all larger sulfur species) is a singlet state. Using the enthalpy of formation of gaseous S₃ as ΔH°_{298} = 141.5 kJ mol⁻¹,³³ it is found that reaction 2 is exothermic by -84 kJ mol⁻¹ in the case of S₂ (³Σ_g⁻) and by -153 kJ mol⁻¹ in the case of S₂ (¹Δ_g). The analogous reactions of Me₂SS with S₃, S₄, etc. are also exothermic.

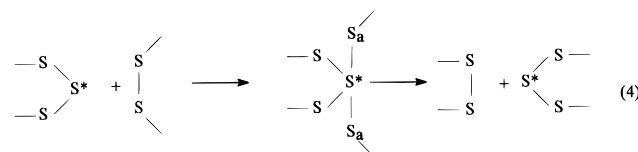

Sulfur transfer reactions of this type have been discussed^{11,34} as possible pathways for the interconversion of sulfur homocycles which occur at ambient or slightly elevated temperatures. Solid c-S₇ decomposes within hours to c-S₈ and polymeric sulfur. In the case of c-S₆, c-S₉, and c-S₁₀ several days are needed for this decomposition.³⁵ Even c-S₈ is converted into S₆, S₇, S₉, and polymeric sulfur on heating to the melting point (120 °C).³⁶ A seemingly reasonable pathway included isomerization of c-S₈ to the hypothetical thiosulfoxide S₇=S, followed by a sulfur atom transfer to another S₈ molecule with formation of S₇ and S₈=S and finally isomerization of the latter to c-S₉.²⁹ However, our present results indicate that the activation energy for the S₈ → S₇=S reaction is probably too high to allow such a reaction at moderate temperatures. The most likely mechanism for the interconversion is the symmetry-

Table 7. S–S Bond Distances *d* and Torsion Angles *τ* at the S–S Bond in Symmetrical Disulfanes RSSR

allowed oxidative addition by insertion of an S atom of molecule A into an SS bond of molecule B followed by dissociation to molecules of type A – S and B + S:^{11,29}

Bonding in RSSR and R₂SS Molecules. The SS bond in thiosulfoxides R₂SS may be considered as either “double”^{3a} or “semipolar”³⁷ depending on the electronegativity of the substituents R:

For R = H the SS bond distance is calculated as 201.8 pm and that for R = Me as 200.3 pm. The experimental value for F₂-SS, derived from microwave spectroscopy,^{4c} is 185.6 pm while the thiosulfite R–O–S(=S)–O–R with R = cyclohexylidene contains an SS bond of length 190.1 pm as determined by X-ray crystallography.⁶ These data can be rationalized by the inductive effect of R on the easily polarizable sulfur electrons in structures I and II.

The bond lengths of disulfanes RSSR also depend on the electronegativity of R as the data in Table 7 show.^{38–40} The values observed range from 206.5 pm for HSSH to 189.0 pm for FSSF. The torsional angles at the SS bonds are all in the usual range of 80–90°. In contrast, the radical ions HSSH^{•+} and MeSSMe^{•+} possess a planar XSSX chain which is explained by the formation of a three-electron *π* bond.^{26d,41} This comparison shows that, in FSSF, for example, with its very short SS bond the reduction in bond length cannot be explained by a simple electrostatic reduction of electron density due to the high electronegativity of the fluorine substituents since this would lead to a planar structure also. Instead, one has to assume a hyperconjugation by which the 3p lone pairs of the sulfur atoms are partly delocalized into *σ** molecular orbitals of those R–S bonds which are located in the same plane. This so-called “gauche effect” has already been discussed for HOOH, FSSF, ClSSCl, and HSSH.^{26b,42} In this way two *π* bonds are created

in planes almost perpendicular to each other. Since the energy of the σ^* orbital will be lower the more electronegative R is, the increasing strength of these additional π bonds on proceeding from R = H and CH₃ via O, N, Br, and Cl to F (Table 7) is to be expected:

Conclusions

Ab initio MO calculations indicate that the barriers for isomerization of HSSH to H₂SS or vice versa are so high that no thermal isomerization is to be expected at temperatures at which H₂S₂ is stable (<50 °C). Simple organic thiosulfoxides are only 80 ± 5 kJ mol⁻¹ less stable than the corresponding

disulfanes. In this case a high barrier to isomerization is calculated for alkyl derivatives, while allyl substituents result in a structurally different transition state which is only 110 kJ mol⁻¹ above the energy of the disulfane. The cyclic structure of this transition state corresponds to the previously intuitively assumed intermediates of this "allyl shift". While it should be possible to isolate and identify H₂SS and R₂SS (R = alkyl) in matrix isolation experiments, bulk quantities of these thiosulfoxides will probably decompose in bimolecular reactions to give the monosulfides and elemental sulfur.
