S Supporting Information

ABSTRACT: We present a colloidal route for the synthesis of ultrathin ZrS₂ (UT-ZrS₂) nanodiscs that are ~1.6 nm thick and consist of approximately two unit cells of S–Zr–S. The lateral size of the discs can be tuned to 20, 35, or 60 nm while their thickness is kept constant. Under the appropriate conditions, these individual discs can self-assemble into face-to-face-stacked structures containing multiple discs. Because the S–Zr–S layers within individual discs are held together by weak van der Waals interactions, each UT-ZrS₂ disc provides spaces that can serve as host sites for intercalation. When we tested UT-ZrS₂ discs as anodic materials for Li⁺ intercalation, they showed excellent nanoscale size effects, enhancing the discharge capacity by 230% and greatly improving the stability in comparison with bulk ZrS₂. The nanoscale size effect was especially prominent for their performance in fast charging/discharging cycles, where an 88% average recovery of reversible capacity was observed for UT-ZrS₂ discs with a lateral diameter of 20 nm. The nanoscale thickness and lateral size of UT-ZrS₂ discs are critical for fast and reliable intercalation cycling because those dimensions both increase the surface area and provide open edges that enhance the diffusion kinetics for guest molecules.

Ultrathin two-dimensional (2D) layered materials such as graphene and transition-metal chalcogenides (TMCs) hold special research interest because of the unique properties associated with their lateral anisotropy. Such materials hold the potential for a wide variety of characteristics, such as facile tuning of the electronic structure and the ability to intercalate a variety of molecules.^{1,2}

In bulk forms, TMCs can exist in a diverse range of polytype structures (1T, 2H, 3R), and their intercalation capabilities are versatile.^{1,3} For example, a typical TMC, titanium disulfide (TiS₂), has been reported to be an efficient lithium storage material,⁴ drawing attention to the relationship between energy storage and intercalation compounds.⁵ If these TMC layered materials can be scaled down to their most basic structural components of either a single layer or a few layers, it may be possible to observe new or pronounced nanoscale effects on their materials characteristics.

Although related nanostructures have been reported,⁶ the synthesis of well-defined ultrathin TMC layered nanomaterials has been a challenging task. Their structures are anisotropic and

Figure 1. (a) Sketch of UT-ZrS₂ nanodiscs dispersed in solution. (b) Low- and (c) high-magnification TEM images of 20 nm single-crystalline UT-ZrS₂ nanodiscs lying flat on the TEM grid. (d) HRTEM image of a nanodisc showing (100) and (110) lattice fringes. (e) HRTEM side-view image of a nanodisc aligned with the electron beam, revealing a disc thickness of ~1.6 nm and 5.8 Å (001) lattice fringes. (f) Ball-and-stick model showing that a single disc corresponds to two unit cells with three S–Zr–S layers (Zr, sky-blue; S, yellow).

have a high probability of containing dangling bonds at peripheral positions. The spheres or wires of TMCs synthesized by Tenne and co-workers⁷ are beautiful structures, but those methods were not developed for the construction of ultrathin 2D disc or sheetlike structures. Hence, facile methods for the synthesis of ultrathin TMCs and the study of any new nanoscale properties associated with those size confinements remain topics of keen interest.

In this communication, we focus on the size-controlled synthesis of ultrathin ZrS₂ (UT-ZrS₂) as a case study among various potential ultrathin TMCs. UT-ZrS₂ nanodiscs were prepared by injecting carbon disulfide (CS₂) into a mixture of zirconium(IV) chloride (ZrCl₄) and oleylamine at 300 °C with stirring under argon atmosphere for 1 h. The H₂S generated by CS₂ and oleylamine reacted with ZrCl₄–oleylamine complexes to form UT-ZrS₂ nanodiscs dispersed in solution (Figure 1a).⁸ The black colloidal products were isolated by centrifugation and washed with a mixture of *n*-butanol and hexane. Figure 1b shows a transmission electron microscopy (TEM) image of UT-ZrS₂ nanodiscs with an average diameter of 20 nm and a narrow size distribution ($\sigma \approx 12\%$). High-resolution TEM (HRTEM) analyses revealed the UT-ZrS₂ nanodiscs to be single-crystalline: a single UT-ZrS₂ nanodisc orthogonal to the direction of the electron beam gave lattice distances of 3.1 and 1.8 Å, corresponding to the (100) and (110) planes (Figure 1d). When oriented

(d) HRTEM side-view image of multiply stacked 1.6 nm thick UT-ZrS₂ nanodiscs showing a regularly spaced gap of ~1.5 nm corresponding to the length of oleylamine surfactant layers.

parallel to the direction of the electron beam (Figure 1e), each ZrS₂ disc was determined to be ~1.6 nm thick with a 5.8 Å (001) lattice plane. This single UT-ZrS₂ disc comprised three layers of S–Zr–S repeating units, corresponding to two unit cells of 1T-type ZrS₂ (Figure 1e,f). X-ray diffraction patterns (Figure S1a in the Supporting Information) indicated that all of the peaks could be indexed to the hexagonal phase with *P3m1* 1T-type ZrS₂ and energy-dispersive X-ray spectroscopy (EDS) measurements confirmed the composition as 1:2 (Figure S1b).

These freestanding individual UT-ZrS₂ nanodiscs were dispersed in solution but easily underwent self-assembly upon a change from a nonpolar solvent such as toluene to a polar solvent such as chloroform. Assembled UT-ZrS₂ nanodiscs were examined by TEM tilting analyses (Figure 2a–c). Figure 2c shows the uniform stacking along the *c* axis, and the spacing between the discs was ~1.5 nm (Figure 2d), which corresponds to the length of the oleylamine surfactant layers.⁹ In polar solvents, UT-ZrS₂ nanodiscs aggregated into stacked structures to bury the non-polar alkyl moieties of oleylamine.

At prolonged reaction times, the nanodiscs increased in lateral size. When the reaction time was increased from 1 to 3 h, the lateral size grew from 20 to 35 nm. After 6 h, we observed disc diameters of 60 nm (Figure 3a–c), but the thickness of the discs remained constant (~1.6 nm). The discs obtained in these studies had relatively uniform lateral sizes. The surfactant and the surface energy appeared to play important roles in the formation of these ultrathin nanodisc structures. According to *ab initio* calculations that examined the structure optimization of ZrS₂ nanodiscs,¹⁰ the surface energies (*S*) of the lateral facets such as (100) or (010) [*S*_{(100)/(010)} = 57.95 meV/Å²] and (110) [*S*₍₁₁₀₎ = 71.76 meV/Å²] were 5–6 times larger than the surface energy of the planar (001) facet [*S*₍₀₀₁₎ = 12.11 meV/Å²]. We largely attribute this difference to the dominance of unstable dangling bonds at the peripheral edges (Figure 3d, purple spheres). This large surface energy difference clearly explains the faster crystal growth rate in the lateral directions.¹¹ In addition, a previous report suggested that linear alkylamines tend to bind strongly to the hexagonal (001) surface, hindering

Figure 3. Size-controlled UT-ZrS₂ nanodiscs and calculated surface energies. (a–c) TEM images of UT-ZrS₂ nanodiscs with three different lateral sizes: (a) 20 nm ($\sigma \approx 12\%$); (b) 35 nm ($\sigma \approx 17\%$); (c) 60 nm ($\sigma \approx 21\%$). (d–f) Schematic diagrams of the UT-ZrS₂ nanodiscs shown as ball-and-stick models: (d) model of a nanodisc showing the dangling bonds at the peripheral positions (purple); (e) planar (001) facet and (f) lateral (100) or (010) facets of a nanodisc, which have calculated surface energies 12.11 and 57.95 meV/Å², respectively.

the growth in the *c* direction.¹² Therefore, the combination of crystal surface anisotropy and the surfactant effect was critical in the formation of UT-ZrS₂ nanodiscs.

Because of the void space between their layers that allows UT-ZrS₂ nanodiscs to function as host materials, we tested their performance in Li⁺ intercalation processes. First, UT-ZrS₂ nanodiscs were prepared and assembled into a coin-shaped electrode after heat treatment of the nanodiscs at 400 °C for 2 h under argon to remove the organic ligands. Subsequently, a half-cell electrochemical measurement was carried out (Figure 4a and Figure S2). The first reversible discharge capacity of 20 nm UT-ZrS₂ nanodiscs was 650 mA h g^{−1}, corresponding to intercalation of 3.8 mol of Li⁺/mol of ZrS₂. The average discharge capacities of 20, 35, and 60 nm UT-ZrS₂ nanodiscs were 586, 527, and 433 mA h g^{−1}, respectively (Figure 4b,d). These values increased as the lateral size decreased, and the smallest nanodiscs (20 nm) showed a 230% enhancement in comparison with the value for bulk ZrS₂ materials (255 mA h g^{−1}).

We also examined the effects of charge and discharge rates in UT-ZrS₂ nanodiscs relative to bulk ZrS₂, when different current densities were applied sequentially (Figure 4c). The current density was increased up to 8-fold from 69 mA g^{−1} to 138, 276, and 552 mA g^{−1} and then decreased back to 69 mA g^{−1} in the reverse sequence (Figure 4c). The retention capacity of the UT-ZrS₂ nanodiscs depended on size and was especially significant at higher current densities. For example, at the highest current density of 552 mA g^{−1} (dashed line box in Figure 4c), the capacity retention values were ~80, ~77, and ~71% for nanodiscs with diameters of 20, 35, and 60 nm, respectively, while that of bulk ZrS₂ was ~45%. After 50 cycles, the 20, 35, and 60 nm nanodiscs showed stabilized capacity retention values of 86, 84, and 80%, respectively (Figure 4c), while the capacity of bulk ZrS₂ declined continuously over time and reached a final value of 39%. The UT-ZrS₂ nanodiscs may acquire these advantageous properties partly because of their large surface areas (171.6, 131, and 78 m² g^{−1} for 20, 35, and 60 nm nanodiscs) relative to bulk ZrS₂ (8.1 m² g^{−1}) (Figure S3).

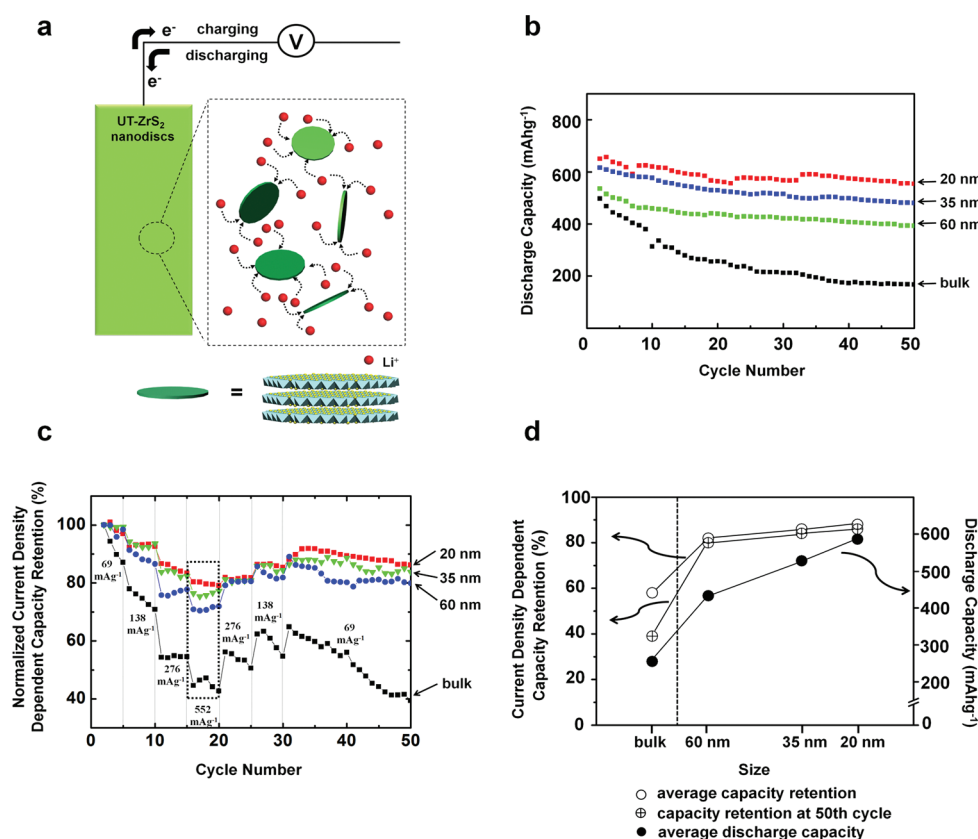

Figure 4. Size-dependent electrochemical properties of UT-ZrS₂ nanodiscs in Li⁺ intercalation studies. (a) Schematic diagram of UT-ZrS₂ nanodiscs as anodic materials. (b) Discharge capacity profiles of the UT-ZrS₂ nanodiscs and bulk ZrS₂. (c) Current-density-dependent capacity profiles of the UT-ZrS₂ nanodiscs and bulk ZrS₂ at current densities of 69, 138, 276, and 552 mA g⁻¹. (d) Summary graphs of Li⁺ charge/discharge capacity changes as functions of nanodisc size.

Among the three sizes of UT-ZrS₂ discs, the smallest (20 nm) showed the best capacity retention after the multiple sequences of fast and slow charging/discharging cycles (Figure 4d). On the basis of our observations and those of other groups, the rapid capacity fade reported for bulk materials is especially common at high current densities.¹³ The size-dependent effects observed for these UT-ZrS₂ nanodiscs clearly demonstrate their merits for high-performance applications. The increased surface area and openness within these nanostructures facilitate Li⁺ insertion and removal and enhance the Li⁺ diffusion kinetics.

In summary, we have demonstrated the synthesis of ultrathin ZrS₂ nanodiscs whose lateral size can be easily modulated. Such ultrathin nanodiscs are highly functional as host materials where nanoscale size effects are significant, and we tested them as anode materials for intercalation processes. Such materials are not limited to the host–guest chemistry shown in this study; these ultrathin 2D materials can be useful in a variety of scientific areas, including catalysis and solid-state lubrication. In addition, this synthetic process is simple and could be easily extended to the preparation of other types of ultrathin metal chalcogenides.
